Authors’ contributions
This work was carried out in collaboration among all authors. Authors HH, XX and JZ designed the study, performed the case analysis, wrote the protocol and wrote the first draft of the manuscript. Authors HH, XX, EL and QW managed the analyses of the case study. Authors XX, XD, KL and JZ managed the literature searches. All authors read and approved the final manuscript.

ABSTRACT
Mandibular osteomyelitis in a patient with psoriasis is an uncommonly clinical manifestation while there is an increasing number of reports and studies on involvements of stomatology in psoriasis, especially the death of a patient via or not via Allogeneic bone marrow transplantation has never been reported. To review the management and possible mechanisms in pathogenesis and treatment of psoriasis, as well as the relative involvements between stomatology and psoriasis the typical case with pictures and files is reviewed and literature is collected. We keep the knowledge that psoriasis is either a primary keratinocyte disorder or an immunocyte-mediated chronic skin inflammatory disease while bone marrow is under suspected for immunopathogenesis. More association of stomatologic conditions with psoriasis is emerging. Conclusively, allogeneic BMT and new knowledge are worth to be stressed by both stomatological and dermatological doctors. Further insights of this kind of auto immunologic disease are under its developing.

1. INTRODUCTION

Psoriasis is common while enigmatic inflammatory skin disorder that affects a population of approximately 2-3% of the world [1-2]. Development of Osteomyelitis in mandible of patient with psoriasis is an uncommonly clinical manifestation that has received little attention ever, but now is gaining some increasing care among the dermatological and stomatological literatures for a reason of the undiscovered essence in pathogenesis mechanism and the development of Allogeneic bone marrow transplantation (BMT) as a positively effective therapeutic strategy [3,4].

Despite the elucidation of many aspects of psoriasis pathogenesis, some puzzling questions remain to be answered. A major question currently debated is whether psoriasis is a primary abnormality of the epidermal keratinocyte, or whether it is a reflection of the imbalance of immunocytes derived from bone marrow'. The authors here are devoting to the reviewing and discussing an irregular case from east China and relevant new knowledge about Psoriasis.

2. MATERIALS AND METHODS

A 27-year-old man had been admitted to the affiliated hospital school of medicine Zhejiang University for two times, respectively during 8-28th September 2007 and from 17th November 2007 to 30th January 2008, diagnosed as Psoriasis, he had a history of 13 years of ankylosing spondylitis, infection in the left cheek, anaemia and chronic active hepatitis B. He died in July 2009.

First-time admission

Due to a 2-year history of repeatedly systemic scaly erythema with a 2-month duration of accelerated recurrence, he was admitted to the department of Dermatology in our hospital from September 8th to 28th 2007. During the past 2 years, he suffered from the scaly erythema in the forehead and scalp, accompanied by mild itching, which gradually spread to the body trunk, limbs, and face. He also suffered from recurrent rashes, without fever, chills, joint pain, or mouth ulcer. After treated with topical steroid ointment and vitamin internal medicine in his local hospital, he recovered a little. However, he was attacked by these again two months ago, with rashes on his whole body. And there was no effect even after taking above medicines. What was worse, rashes and itching increased significantly in the past 2 weeks. So, he was enrolled as an inpatient to receive further therapy being diagnosed as “regular Psoriasis”. Additionally, he received two times of Abscessincision surgery in his left face one month ago and then was extracted his left first mandibular molar 2 weeks ago. There were swelling and pain in his left face 2 days ago, with moderately limited mouth opening that was only 27 mm width, he also got a small bug shape swelling of 1.5 cm in the skin, yellow and soft of the left cheek (Fig. 1). Fistula and pus discharge could be seen in the oral vestibular of the left mandibular molar. Besides, he had got anaemia for more than 10 years and hepatitis B over 20 years, with a normal liver function that was checked regularly. After incision and drainage treatment as well as anti-infective medicine, he recovered much with reduced swelling.

Fig. 1. The patient’s fistula and swelling from mandibular osteomyelitis in his left cheek

Laboratory data revealed the following values: PL73000/ml (normal values, 100000-300000/ml), Hb6.8g/dl, RBC2.44x1012, WBC5.7x109, CRP97.5 mg/L, N (Neutrophils) 67.5%, HBV-DNA 4.13 x10⁶ copy/ml. Plasma fibro Fibrinogen (FBG) 6.4. Melt beads pro 3.93. Iron transferrin protein receptor 6.92 mg / l. Albumin ↓, Albumin to Globulin 0.92 (normally 1.50-2.50), Vit B12 152 (normally 187-1059 pg/ml), Iron transferrin protein 1.68 (normally 2.12-3.60 g / l). Report for his bone marrow aspiration was: Iron deficiency anaemia manifestation of bone marrow. Report
for enhanced spiral CT scan of his jaw was: Left side muscle cystic lesion, a large cyst with infection probably (Fig. 2). Panoramic X-ray showed osteomyelitis in his left mandible (Fig. 3). Ultrasonic B for his left cheek reported: The left cheek and left mandible shallow fluid exudate. Pancreatic splenic Ultrasonic B and EKG reported: no obvious abnormalities.

Second-time admission

After the remission of his last psoriasis, he was admitted again into our hospital for an over ten-day accelerated recurrence during 17th November 2007 till to 30th January 2008, after no therapeutic effect from his local Shengzhou City People’s hospital. His clinical signs and symptoms were fever, joint pain, and increased erythema. The swelling and purulent secretion in his left cheek brought him a 10 mm width mouth opening. Report of his ultrasonic B from Shengzhou City People’s hospital was: increased size of liver resulted from chronic liver disease. CT scan reported a probable left Mandible Osteomyelitis. Inpatient CT in our hospital reported a probability of chronic infectious diseases in the left mandibular body and ramus. Via Bone marrow aspiration, the graphic report for the cellular morphological examination of bone marrow was "Secondary increase in plasma cells. Poor platelet generation ability of megakaryocytes." And the biopsy report for BB plastic embedding of bone marrow was “Reactive Increase in plasma cells and deficiency of iron in bone marrow”. Result of purulent secretion culture was MRSA (Staphylococcus aureus) +. Due to poor spirit, sleep quality and general condition not suitable for surgery, he received local irrigation and rinse treatment with Clindamycin from the department of stomatology.

3. RESULTS

Years of follow the patient remaining in remission over the 10 years of his psoriasis. However, in Tamas's report, the psoriasis of his patient who received Allogeneic BMT for his severe aplastic anaemia which disappeared in no time after Allogeneic BMT has been in remission for more than 10 years. Tamas indicated that, as complete donor chimerism was proved on day 342, it was more likely that a substantial alteration in patient’s cellular immunity was the reason for the complete resolution of the first one’s psoriasis.

Tamas [4] described two psoriatic patients. The above-mentioned one received Allogeneic BMT who recovered from his psoriasis completely and has been in remission for more than 10 years. The second patient received Autologous BMT whose psoriasis returned after 21 months of remission. Tamas indicated that, as complete donor chimerism was proved on day 342, it was more likely that a substantial alteration in patient’s cellular immunity was the reason for the complete resolution of the first one’s psoriasis.

There are two main hypotheses currently holding a view on the psoriasis pathogenesis either as a primary keratinocyte disorder or as an immunocyte-mediated chronic skin inflammatory disorder. There is more medication-related rather than Psoriasis-related osteomyelitis reported [7]. Basically, since Schon, more researchers [2,8] also indicated the involvement of bone marrow in the immunopathogenesis of psoriasis and suggested a mechanism mediated by certain inflammatory or haematopoietic cytokines in the bone marrow microenvironment played a role in psoriasis.

As for the essence in pathogenesis mechanism and therapeutic strategies, additional study [3] presented that elevation of HES1 mRNA expression suggested a potential role of the Notch signalling pathway in psoriasis, and target therapy utilizing anti-tumour necrosis factor α as reported [6] and alefacept [8] could also be referred.

In brief, a vital and effective method for investigation is to launch a foundation of an ideal animal model. In fact, since 1940s, the progress in animal model of psoriasis as skin lesion of psoriasis-like histology has been conducted from topical drug administration to local or intravascular injection of T cells [9] which were all included in a limitation as a local and temporal lesion model, far from being a systematic and sustainable satisfactory subject to promisingly meet and propel the Psoriasis researches including gene therapy, T cell vaccine, and drug screening. Hopefully, given that bone-marrow
derivative pathogenesis was confirmed, a substantially novel animal model would be facilitated for hematopoietic stem cell therapy to solute Psoriasis.

With regard to the latest reports on the relationships between psoriasis and stomatology, there are four literature talked about the oral manifestations and involvements with psoriasis [10,11], three articles discussed the association of psoriasis with dental caries and periodontitis [12,13] and two declarations about the treatment of multiple diseases involving psoriatic disorder and Behçet's disease [14], as well as the STAT3 genetic variants in the susceptibility to these two medical conditions [15].

A mutual triggering of one disease triggered by the other disease drug between psoriasis agents and Behçet's disease drugs seems to be presented and concerned by Ophthalmological and Pharmacological experts respectively [14,16], in these investigations, they in sighted into Behçet's disease or oral mucositis with psoriasis. Briefly, dental Infection was viewed as a triggering factor in Palmoplantar Pustulosis [17]. Oral candidiasis was also evaluated in patients with psoriasis [18]. To decrease some mortality, allogeneic BMT and new knowledge are worth to be considered by both stomatologists and dermatologists.

5. CONCLUSION

Psoriasis is either a keratinocyte disorder or an immunocyte-mediated chronic skin inflammatory disease. There is more medication-related rather than Psoriasis-related osteomyelitis reported [10]. In this unusual mandibular osteomyelitis in concurrence with Psoriasis, the exact mutual pathogenesis remains unclear. The bone marrow in which certain micro-environmental inflammatory or haematopoietic cytokines might play a role is under suspicion for Psoriasis’s immunopathogenesis [6,9]. Further insights of this severe auto immunologic disease are marching. To decrease some mortality, allogeneic BMT and new knowledge are worth to be considered by both stomatologists and dermatologists.

CONSENT AND ETHICAL APPROVAL

As per university standard guideline participant consent and ethical approval has been collected and preserved by the authors.
